

7. PROSTATE CANCER

7.1. SUMMARY

Prostate cancer was the most common cancer in men, accounting for 23% of all malignant neoplasms, excluding non-melanoma skin cancer, in men in Ireland (Table 7.1). The average number of new cases diagnosed each year was 2,550. Between 1995 and 2007, the number of new cases more than doubled, increasing by approximately 7% per annum. From 1995 to 2001, the number of new cases diagnosed per annum rose by approximately 9% in RoI and by 2% in NI. From 2002 to 2007 the annual increase was 5% in RoI and 6% in NI.

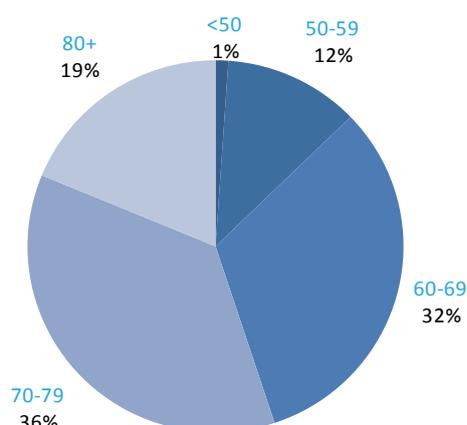

The risk of developing prostate cancer up to the age of 74 was 1 in 13 and was higher in RoI than in NI. At the end of 2008, 5,235 males aged under 65 and 17,829 aged 65 and over were alive up to 15 years after their prostate cancer diagnosis.

Table 7.1 Summary information for prostate cancer in Ireland, 1995-2007

	Ireland	RoI	NI
% all new cancer cases	17%	18%	14%
% all new cancer cases excluding non-melanoma skin cancer	23%	25%	19%
average number of new cases per year 1995-2007	2550	1900	649
average number of new cases per year 1995-2001	1955	1439	517
average number of new cases per year 2002-2007	3243	2439	804
cumulative risk to age 74	8.0%	8.9%	6.0%
15-year prevalence (1994-2008)	23064	17430	5634

Prostate cancer is predominantly a disease of old age. Just over 1% of cases presented in those aged under 50, while 87% occurred in those aged 60 and older (Figure 7.1). Age at diagnosis was slightly older in NI than in RoI, with 60% aged 70 and over at diagnosis in NI compared with 53% in RoI.

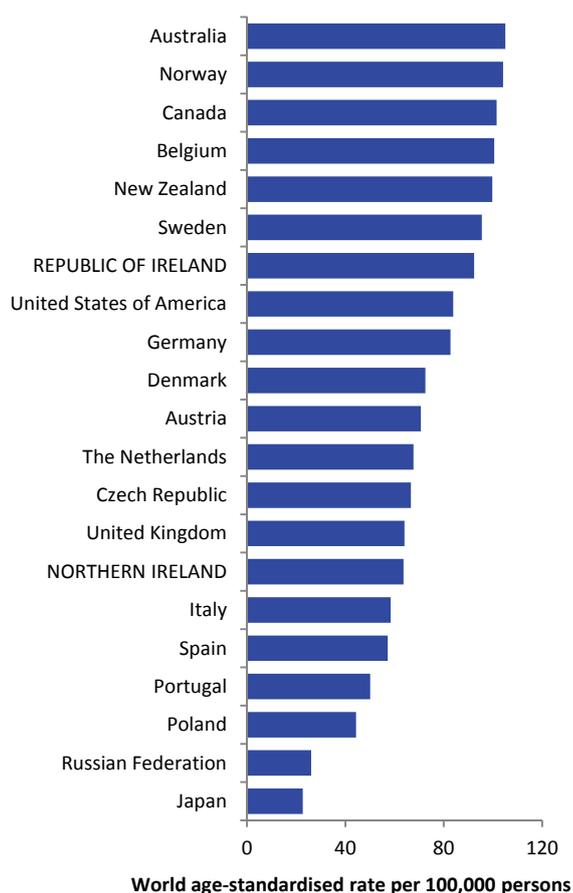

Figure 7.1 Age distribution of prostate cancer cases in Ireland, 1995-2007

7.2. INTERNATIONAL VARIATIONS IN INCIDENCE

Considerable variation exists in prostate cancer incidence rates among developed countries. Estimates for 2008 ranged from 105 per 100,000 men in Australia to 23 per 100,000 in Japan (Figure 7.2). The rate in RoI was in the upper third of the range, while that in NI was in the lower third.

Source: GLOBOCAN 2008 (Ferlay et al., 2008) (excluding RoI and NI data, which is derived from cancer registry data for 2005-2007)

7.3. RISK FACTORS

Table 7.2 Risk factors for prostate cancer, by direction of association and strength of evidence

	Increases risk	Decreases risk
Convincing or probable	Family history of prostate cancer ^{1,2}	Foods containing lycopene ^{8,9}
	Height/tallness ³	
	Arsenic and arsenic compounds ⁴	
	Cadmium and cadmium compounds ⁴	
Possible	Obesity (aggressive prostate cancer) ⁵	Obesity (non-aggressive prostate cancer) ⁵
	Tobacco smoking ⁶	Selenium or foods containing selenium ^{9,10}
	Insulin-like growth factor-1 (IGF-1) ⁷	Soya and soya food products ^{11,12}
		Aspirin and other non-steroidal anti-inflammatory drugs ¹³

¹ One or more relative(s) with prostate cancer; ² Bruner et al., 2003; ³ Zuccolo et al., 2008; ⁴ Straif et al., 2009; ⁵ Giovannucci and Michaud, 2007; ⁶ Huncharek et al., 2010; ⁷ Rowlands et al., 2009; ⁸ lycopene is a carotenoid found in tomatoes and tomato products, such as soup and puree; ⁹ World Cancer Research Fund / American Institute of Cancer Research, 2007; ¹⁰ Jiang et al., 2010; ¹¹ Hwang et al., 2009; ¹² Yan and Spitznagel, 2009; ¹³ Mahmud et al., 2010

The chances of a man developing prostate cancer are approximately doubled if he has a relative with the disease. Despite extensive study, relatively few other risk factors for prostate cancer have been firmly established (Table 7.2). Taller men appear to have higher risk, although height *per se* is unlikely to affect a man's chances of developing the cancer: instead it probably points to relevant childhood exposures. One possibility is that the association operates through the insulin-like growth factor system, which plays a key role in cell proliferation, differentiation and apoptosis. Positive associations have been reported between prostate cancer and circulating levels of insulin-like growth factor 1.

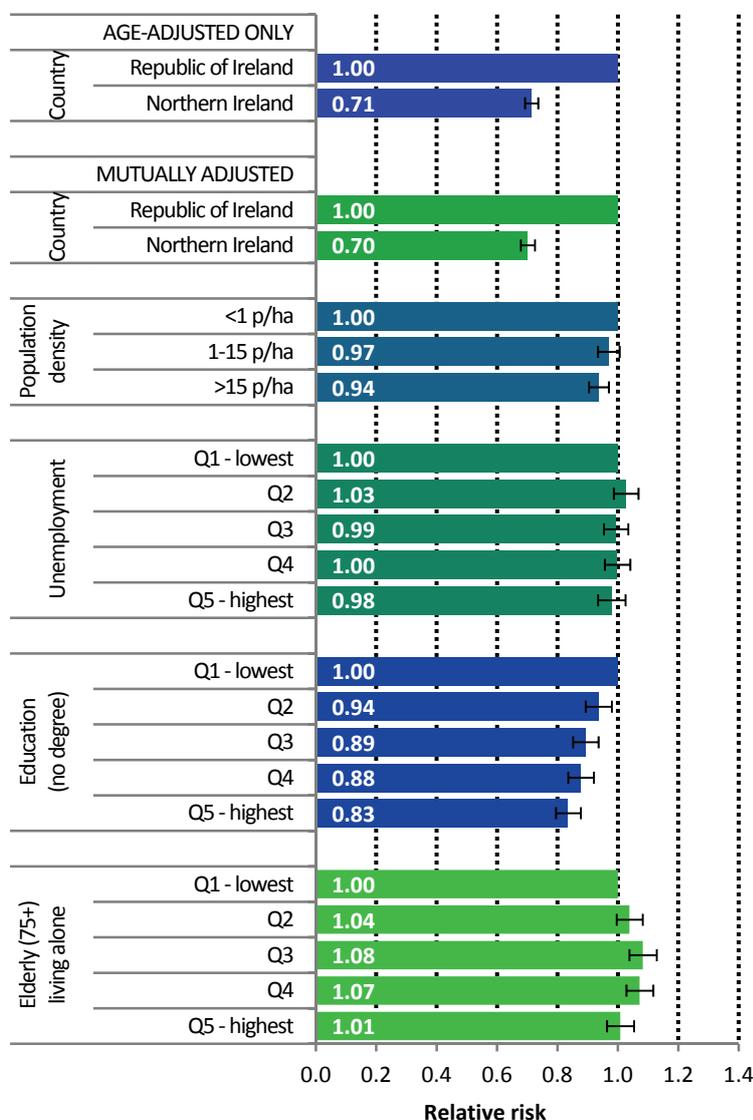

There is limited evidence that exposure to arsenic and inorganic arsenic compounds (through occupational inhalation or ingestion in food or drinking water) and cadmium and cadmium compounds (via occupational use), are a cause of prostate cancer.

Some aspects of diet may influence risk. Higher intake of the carotenoid lycopene is associated with decreased risk in many studies. Risk may be reduced in men, especially those from Asian populations, who consume more tofu and soya food products. While observational studies suggest that higher intake of selenium or selenium-rich foods is also inversely associated with prostate cancer, two trials found no effect of selenium supplementation.

Obesity may be associated with reduced risk of non-aggressive prostate cancer but, since the opposite has been suggested for aggressive disease, the observations could be due to a detection bias relating to the ability to detect prostate cancer in obese men (Buschemeyer and Freedland, 2007). While current smoking *per se* does not appear to be associated with risk, risk may be elevated among smokers with higher levels of exposure. Meta-analyses suggest the possibility that regular use of aspirin and other non-steroidal anti-inflammatory drugs could be associated with reduced risk of prostate cancer overall, and of advanced cancers specifically, but there are inconsistencies and limitations in the evidence.

7.4. SMALL GEOGRAPHIC AREA CHARACTERISTICS AND CANCER RISK

Figure 7.3 Adjusted relative risks (with 95% confidence intervals) of prostate cancer by socio-economic characteristics of geographic area of residence

The risk of prostate cancer in NI was 29% lower than in ROI, with variations between the two countries with regard to socio-economic factors and population density having a minimal impact on this difference (Figure 7.3).

There was a weak relationship between prostate cancer and population density, with men living in the least densely populated areas at greater risk. Unemployment was not associated with prostate cancer risk.

The strongest area-based factor in prostate cancer risk was education; men resident in areas with a smaller proportion of people with degree level qualifications had a 17% reduced risk compared to those living in areas with the highest proportion of people with degree level qualifications.

Men resident in the 3rd and 4th quintiles of the proportion of elderly people living alone indicator had the highest risk of prostate cancer.

7.5. MAPPING AND GEOGRAPHICAL VARIATION

For the period 1995-2007, prostate cancer exhibited a strong geographical pattern with a number of discrete areas of higher risk, mainly in the west.

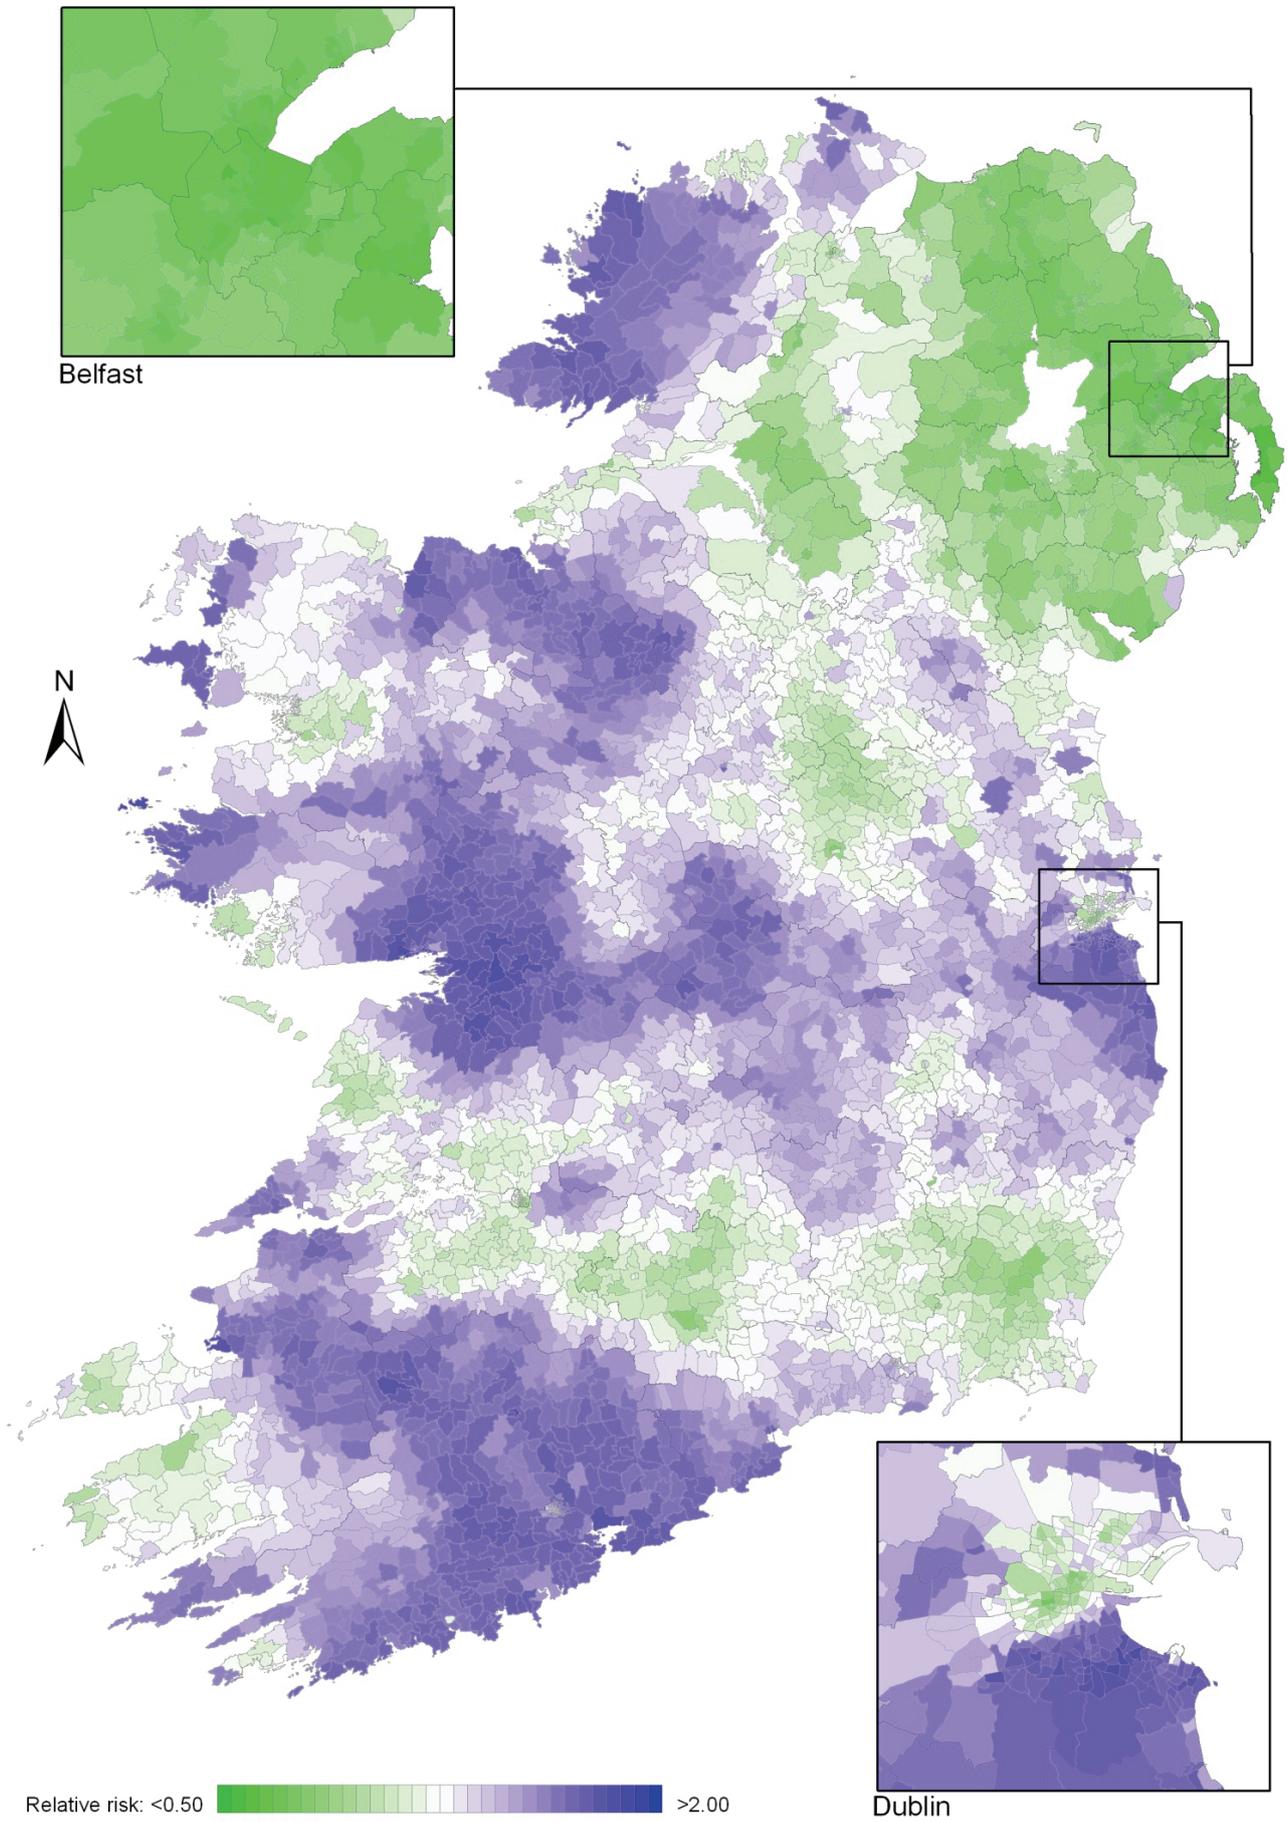

For all time periods, relative risk was lower in NI than in RoI (Map 7.1).

During 1995-2001, the relative risk tended to be higher in the south and east of Ireland. Areas of higher risk were also found in Donegal, Sligo, Galway, Clare and north Kerry (Map 7.2).

During 2002-2007 risk tended to be higher in a number of areas in the west and north-west, including Donegal and across the midlands to the east coast (Map 7.3). Risk was higher in the south of Dublin city compared to the central and northern parts.

8. NON-HODGKIN'S LYMPHOMA

8.1. SUMMARY

Non-Hodgkin's lymphoma (NHL) consists of a group of more than 20 different malignant lymphoproliferative diseases that originate from lymphocytes. NHL was the fifth most common cancer in Ireland, accounting for 3.4% of all malignant neoplasms, excluding non-melanoma skin cancer, in women and 3.6% in men (Table 8.1). The average number of new cases diagnosed each year was approximately 354 in women and 392 in men. During 1995-2007, the number of new cases diagnosed increased by approximately 3% per annum overall.

The risk of developing NHL up to the age of 74 was 1 in 102 for women and 1 in 80 for men, and was higher in NI than in RoI for both males and females. At the end of 2008, 1,255 females and 1,607 males aged under 65, and 1,477 females and 1,266 males aged 65 and over, were alive up to 15 years after their NHL diagnosis.

Table 8.1 Summary information for non-Hodgkin's lymphoma in Ireland, 1995-2007

	Ireland		RoI		NI	
	females	males	females	males	females	males
% of all new cancer cases	2.5%	2.6%	2.3%	2.5%	2.9%	2.8%
% of all new cancer cases excluding non-melanoma skin cancer	3.4%	3.6%	3.2%	3.5%	3.8%	3.8%
average number of new cases per year	354	392	224	265	130	127
cumulative risk to age 74	1.0%	1.2%	0.9%	1.2%	1.1%	1.3%
15-year prevalence (1994-2008)	2732	2873	1782	1944	950	929

Age at diagnosis of NHL was younger for men than for women—43% of cases presented in men under 60 compared to 33% of women (Figure 8.1). Approximately 17% of women and 10% of men were aged 80 years or older at diagnosis. Age at diagnosis was also slightly younger in RoI than in NI.
